

# Testing a dual isotope model to track carbon and water gas exchanges in a Mediterranean forest

Ripullone F<sup>(1)</sup>, Guerrieri MR<sup>(1)</sup>, Saurer M<sup>(2)</sup>, Siegwolf R<sup>(2)</sup>, Jäggi M<sup>(2)</sup>, Guarini R<sup>(1)</sup>, Magnani F<sup>(3)</sup>

Due to climate change, drier summers have been observed over the last ten years in Mediterranean areas. Increasing drought levels may have a different weight in influencing the stomatal versus photosynthetic activity of forests, altering the water-use efficiency (*i.e.*, WUE, the amount of carbon gain per water lost) and, consequently, the global carbon balance. By combining leaf gas exchanges and leaf carbon/oxygen isotope measurements, we tested under Mediterranean conditions a semi-quantitative dual isotope model to track adjustments in stomatal conductance ( $g_s$ ) and maximum CO<sub>2</sub> assimilation at saturating light ( $A_{max}$ ) in response to changes in air and soil water availability. The experiment was established at Allumiere site (Rome, Italy) over the course of two consecutive years. There, we modified the amount of precipitation reaching the soil on water depleted (D) and watered (W) replicate plots (~100 m<sup>2</sup>) of an *Arbutus unedo* L. forest using a system of rain gutters and sprinklers, respectively. Changes in soil water availability affected  $g_s$  and  $A_{max}$  in parallel. As an application of the model, we found that, in response to reduced air and soil water availability, constant carbon ( $\delta^{13}C$ ) and increasing oxygen ( $\delta^{18}O$ ) isotope values were consistent with a parallel decline of either  $g_s$  and  $A_{max}$ . As a result of parallel decline, WUE did not differ or only slightly differed between treatments, in contrast with most of the studies that found a wide-spread increase of WUE in response to enhanced drought. This study highlights the potentiality of the dual isotope model to provide insights of forest ecosystem functioning in Mediterranean environments.

**Keywords:** Carbon assimilation, Drought, Isotope model, *Arbutus unedo*, Stomatal conductance, Water-use efficiency.

## Introduction

In a Mediterranean-type climate, forest ecosystems are typically subjected to high temperature and scarce soil water availability during most of the summer. Moreover, due to the impact of climate change, more extreme drought periods are expected for the

coming decades as a consequence of reduced precipitation during summers (IPCC 2007, Sarris et al. 2007). Under such conditions, gas exchanges will be largely limited by the availability of water for transpiration (Rambal et al. 2003). Partial stomatal closure is one of the key mechanisms adopted by trees to save water and to avoid cavitation risks (Tyree & Sperry 1989, Irvine et al. 1998, Cinnirella et al. 2002).

In turn, climate change may result in a negative impact on plant carbon assimilation through the increase of stomatal limitation to photosynthesis (Jarvis & Davies 1998, Lawlor & Cornic 2002). Thus, by the adjustments of stomatal conductance ( $g_s$ ) and maximum CO<sub>2</sub> assimilation ( $A_{max}$ ) in response to increasing drought will depend the amount of carbon that can be assimilated by trees. Additionally, these adjustments will determine the ability of Mediterranean forests to counterbalance the negative effect of increasing drought on growth and, consequently, on the gross primary production (GPP - Rambal et al. 2003). In semi-arid environments, the shape and the values of  $A_{max}$  and  $g_s$  will also determine the intrinsic water-

use efficiency (WUE<sub>int</sub>), a component of the long-term water-use efficiency (WUE<sub>T</sub>, the amount of carbon gain per water lost). WUE<sub>int</sub> is also a key parameter for deriving the productivity and the amount of carbon assimilated by forests (Ripullone et al. 2004).

Previous models were based on the simplifying assumption of a constant linear relationship between  $g_s$  and  $A_{max}$ , with a simple dependence upon vapour pressure deficit (VPD - Wong et al. 1979). However, other studies have shown that this relationship is influenced by other environmental stresses such as soil moisture (Ball et al. 1987, Leuning 1995). Non-stomatal limitations (*i.e.*, mesophyll conductance and biochemical reactions - Rubisco, etc.) may be involved even under mild-moderate water stress (Flexas & Medrano 2002, Grassi & Magnani 2005), thus changing the  $A_{max}$  and  $g_s$  relationship (and consequently the WUE).

The use of stable carbon ( $\delta^{13}C$ ) isotope as a powerful tool for investigating the balance between  $A_{max}$  and  $g_s$  (see isotope theory) has grown steadily during the past two decades. The positive relationship between WUE and  $\delta^{13}C$  arises through their independent linkages to the ratio of internal to ambient CO<sub>2</sub> concentrations ( $c_i/c_a$  - Farquhar et al. 1989, Guehl et al. 1995). To differentiate between the changes in  $\delta^{13}C$  driven by  $A_{max}$  or  $g_s$ , Scheidegger et al. (2000) proposed the incorporation of  $\delta^{18}O$  in a dual quantitative model. In fact,  $\delta^{18}O$  is affected by transpiration rates, which is closely correlated with  $g_s$  (Barbour & Farquhar 2000).

The broader purpose of this study was to test in the Mediterranean environment a dual isotope conceptual model (Scheidegger et al., 2000) to infer CO<sub>2</sub> and H<sub>2</sub>O gas exchange activities of *Arbutus unedo* forest. To this aim,  $\delta^{13}C$  and  $\delta^{18}O$  in combination with direct measurements of leaf gas exchanges have been employed to give insight into the adjustments of  $g_s$  and  $A_{max}$  resulting from different vapor pressure deficit (VPD) and soil water availability; this latter was changed by an experimental manipulation of the amount of precipitation reaching the soil. Furthermore, based on the observed variations in  $g_s$ ,  $A_{max}$  and  $\delta^{13}C$ , the effects of water restriction on WUE were also examined.

## Isotope theory

### Carbon and oxygen isotopes

The stable isotope technique has been revealed to be an important tool in identifying medium and long-term effects of environmental factors on CO<sub>2</sub> and H<sub>2</sub>O gas exchanges in plants. The carbon isotope composition ( $\delta^{13}C$ ) of leaf organic matter reflects the fractionation processes occurring during

the diffusion of  $^{12}\text{CO}_2$  and  $^{13}\text{CO}_2$  through stomatal pores and photosynthetic assimilation. In  $\text{C}_3$  plants, discrimination against  $^{13}\text{C}$  is linked to photosynthesis via  $c_i/c_a$ , the ratio of intercellular ( $c_i$ ) to atmospheric ( $c_a$ )  $\text{CO}_2$  concentrations as described by Farquhar et al. (1982 - eqn. 1):

$$\delta^{13}C_{leaf} = \delta^{13}C_{atm} - a - (b-a) \cdot (c_i/c_a)$$

where  $\delta^{13}C_{leaf}$  and  $\delta^{13}C_{atm}$  are the carbon isotope compositions of leaf organic matter and atmospheric  $\text{CO}_2$ , respectively, and  $a$  and  $b$  are fractionation factors occurring during diffusion of  $\text{CO}_2$  through stomata pores (-4‰) and enzymatic C-fixation by Rubisco (-27‰), respectively. According to equation 1, a lower  $c_i/c_a$  ratio results in an increased  $\delta^{13}C_{leaf}$  due to a lower discrimination ( $\Delta$ ) against  $^{13}\text{CO}_2$ . Environmental factors such as water availability and irradiance can cause variations of  $c_i/c_a$ , mainly through their effects on both stomatal conductance ( $g_s$ ) and photosynthetic activity (Farquhar et al. 1989).

$\delta^{13}\text{C}$  has largely been used as a proxy for long-term water-use efficiency (WUE, the amount of carbon gained per water transpired) of  $\text{C}_3$  plants (Farquhar et al. 1989), thanks to their independent linkages to  $c_i/c_a$  (eqn. 2):

$$WUE = (1 - \Phi) \cdot c_a (1 - c_i/c_a) / 1.6 VPD$$

where VPD is the vapour pressure difference between the intercellular spaces and the atmosphere and  $\Phi$  is the fraction of carbon respired by the plants. However, a simpler concept of WUE is often used (*i.e.*, intrinsic water-use efficiency ( $WUE_{int} = A/g_s$ , the ratio of  $\text{CO}_2$  assimilation to stomatal conductance) or instantaneous water-use efficiency ( $WUE_{inst} = A/E$ , the ratio of assimilation to leaf transpiration) when the leaf-to-air vapour pressure difference is known (Farquhar et al. 1989). These are both components of long-term WUE. Although it successfully captures WUE trends,  $\delta^{13}\text{C}$  fails to account for factors responsible for variations in WUE. These variations can be the result of changes in  $g_s$  or  $A$ . For example, an increase in  $\delta^{13}\text{C}$ , interpreted as a reduction in  $c_i$  and an improvement in WUE in the Farquhar model, can be the result of either: (1) reduced  $g_s$  (at constant  $A$ ); or (2) increased  $A$  (at constant  $g_s$ ).

The oxygen isotope composition ( $\delta^{18}\text{O}$ ) of leaf organic material can be used for distinguishing between possible causes of variation in  $\delta^{13}\text{C}$ , thanks to the link of  $\delta^{18}\text{O}$  with the isotopic fractionation of water during transpiration in leaves. During transpiration, molecules of water containing lighter isotopes ( $\text{H}_2^{16}\text{O}$ ) tend to diffuse faster from the site of evaporation to the atmosphere. In this way, water becomes enriched in the

**Fig. 1** - The conceptual isotope model from Scheidegger et al. (2000): scheme of the eight scenarios from a) to h) based on all the likely  $\delta^{13}\text{C}$ - $\delta^{18}\text{O}$  combinations (model input). The changes are shown by the arrows. Relative humidity (rH) is derived from  $\delta^{18}\text{O}$ , while  $c_i$  is derived from  $\delta^{13}\text{C}$  (symbols: ↑, ≈ and ↓ represent increase, no response and decrease in levels, respectively). For each scenario there are two possible cases, indicated as 1 and 2, with corresponding changes in  $A_{max}$  and  $g_s$ . The model output at the bottom gives relative  $A_{max}$  and  $g_s$  based on the rH changes.

heavier isotopes of  $^{18}\text{O}$ , compared to water coming from the soil. The oxygen isotopic composition of leaf water at the sites of evaporation ( $\Delta_e$ ) is expressed as follows (Craig & Gordon 1965, Dongmann et al. 1974, Farquhar & Lloyd 1993 - eqn. 3):

$$\Delta_e = \epsilon^* + \epsilon_k + (\Delta_v - \epsilon_k) \cdot e_a/e_i$$

where  $\Delta_v$  is the oxygen isotopic composition of water vapour in the air,  $\epsilon^*$  is the temperature-dependent fractionation associated with the lower vapour pressure of  $\text{H}_2^{18}\text{O}$  compared to that of  $\text{H}_2^{16}\text{O}$ ,  $\epsilon_k$  is the kinetic fractionation during evaporative water diffusion through the stomata and boundary layer, and  $e_a/e_i$  are the vapour pressures in the atmosphere and intercellular air spaces, respectively.

Thus, according to this equation, the degree of leaf water enrichment depends on the rH. The latter represents the evaporative driving force, and a reduced rH causes an increase of  $\delta^{18}\text{O}$  in the leaf water. This enrichment is then expected to be reflected in the organic matter (De Niro & Epstein 1979, Yakir 1992, Farquhar et al. 1998, etc).  $\delta^{18}\text{O}$ , determined in this manner, has often been found to be negatively correlated with  $g_s$  (Barbour & Farquhar 2000, Grams et al. 2007).

### Linking $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ in a dual isotope conceptual model

The dual isotope conceptual model pro-

posed by Scheidegger et al. (2000) represents a simplified tool to infer  $A_{max}$  and  $g_s$  from the variation of  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  in plants. Fig. 1 shows all combinations of  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  values in eight likely scenarios where the outputs of the model (*i.e.*,  $g_s$  and  $A_{max}$ ) are selected on the basis of changes in rH. Different environmental conditions can cause higher (↑), lower (↓) or similar (≈)  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  values. As an example, we refer to scenario b) where both  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  values increased. We know from the increase in  $\delta^{18}\text{O}$  that rH must have increased, while from the increasing  $\delta^{13}\text{C}$ , we infer a decreasing  $c_i$ . This reduction is explained by two possible cases: (1)  $A_{max}$  ↑ and  $g_s$  ≈ or (2)  $A_{max}$  ≈ and  $g_s$  ↓. Because plants in dry air tend to close their stomata, we choose case (2) as it is physiologically more plausible than case (1). Thus,  $\delta^{13}\text{C}$  reflects variation in  $c_i$ , while  $\delta^{18}\text{O}$  is affected by variation in rH. This variation, in turn, drives changes in transpiration rates and  $g_s$ .

## Materials and methods

### Study site and experimental design

The research was carried out in a drought-prone 50 ha of Mediterranean macchia. The site was dominated by the coppice *A. unedo*, which covers 65% of the surface. The study site, environmental conditions and stand characteristics are detailed in Tab. 1.

Two different levels of volumetric soil water content (SWC, volume of water per

volume of soil, multiplied by 100) have been imposed by an alteration of the amount of precipitation reaching the soil. This was done during the summers of 2004 and 2005 (June to August) on three replicated plots (~100 m<sup>2</sup>). A mean value of 7% in SWC was obtained by partial rain exclusion (-20%), using a system of pipes suspended about 1.8 m above the forest floor (water-depleted plots, D). A mean value of 14% in SWC was

obtained by adding water through a sprinkler net to simulate rain events (watered plots, W). A 10% threshold of SWC, established in a pre-treatment experiment, represented the dry (below) and well-watered (above) conditions (Ripullone et al. 2009).

#### Water relations and gas exchange measurements

SWC was measured within the D and W treatments by probes (Campbell Scientific, INC, Logan, Utah, USA). These probes consisted of two 30 cm long stainless steel rods, fully inserted into the soil at six different locations per replicate. The time domain reflectometry (TDR) method was used to translate the readings in SWC (Topp & Davis 1985).

Eight intensive field campaigns were carried out during 2004 and 2005 to assess plant water status. Predawn leaf water potential ( $\Psi_{pd}$ ) was measured on six to eight experimental trees per replicate in D and W plots. For each tree we measured five fully expanded leaves with a Scholander-type pressure chamber (PMS Instruments, Corvallis, OR, USA).

Maximum CO<sub>2</sub> assimilation at saturating light ( $A_{max}$ ) and stomatal conductance ( $g_s$ ) were measured using a portable infrared gas analyzer (LI-6400 Li-cor, Lincoln, NE, USA). Measurements were performed on 10 sunlit leaves of six trees growing in the central portion of each replicated plot to avoid the "edge effect". Hours between 11:30 am and 15:30 pm on cloudless days were chosen for all measurements. This is when environmental conditions were most stable and when photosynthetic photon flux density (PPFD) was above 1200  $\mu\text{mol m}^{-2} \text{s}^{-1}$  (above

saturating light conditions for *A. unedo* - data not shown). In order to take into account the effect of vapour pressure deficit (VPD) in driving variation in WUE, we considered the instantaneous WUE ( $WUE_{inst}$ ), calculated from gas exchange measurements, as the ratio of  $A_{max}$  to leaf transpiration rate (E).

#### Carbon and oxygen isotope analysis

Six samples of non-fully expanded leaves were collected from each replicate plot in five field campaigns (June, July 2004 and June, July, September 2005) to measure carbon ( $\delta^{13}\text{C}$ ) and oxygen ( $\delta^{18}\text{O}$ ) isotopes. Leaf samples were collected from the same shoots where gas exchange measurements were performed.

Bulk leaf samples were dried, ground to a fine powder and then weighed in tin capsules, using a value of 0.6-0.8 mg for  $\delta^{13}\text{C}$  and 1.1-1.3 for  $\delta^{18}\text{O}$ . Bulk leaf material was combusted to CO<sub>2</sub> for carbon isotope analysis in an elemental analyzer (EA-1108, Carlo Erba, Italy), which was connected to a mass spectrometer (Delta-S Finnigan MAT, Germany) via a variable open split interface (CONFLO II Finnigan MAT, Germany). For determination of  $\delta^{18}\text{O}$ , leaf bulk material was pyrolyzed (Saurer et al. 1998) to CO with an elemental analyzer (EA-1108, Carlo Erba, Italy), connected to the same mass spectrometer.

$\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  were calculated as:

$$\delta x = [R_{sample} / R_{standard} - 1] \times 1000$$

where  $R$  is the isotope ratio and  $^{13}\text{C}/^{12}\text{C}$  or  $^{16}\text{O}/^{18}\text{O}$  refer to the sample and to the standard, respectively. The isotope values are expressed in delta notation, with V-PDB for

carbon and VSMOW for oxygen. The accuracy of the method was  $\pm 0.2\text{‰}$  for  $\delta^{13}\text{C}$  and  $\pm 0.2\text{‰}$  for  $\delta^{18}\text{O}$ .

**Statistical analysis**

Values of treatments (W, D) are presented as the mean  $\pm$  standard error and compared using the Student-Newman-Keuls test. Statistical significance was defined as  $P \leq 0.05$  and  $P \leq 0.01$ . Linear regressions were analysed using Pearson correlation coefficients. All statistics were computed with the SPSS statistical package (SPSS, Chicago, IL).

**Results**

*Carbon and water relations*

As a consequence of treatments, significant differences in soil water content (SWC) emerged between water depleted (D) and watered (W) plots, although such differences were higher in 2005 than 2004 (Tab. 2).

In general, predawn water potentials ( $\Psi_{pd}$ ) reflected the SWC conditions during the two years of the experiment (Tab. 2). Significant differences in  $\Psi_{pd}$  were observed in the summer of 2004 and 2005 between D and W plots ( $P < 0.05$ ), demonstrating the effectiveness of the applied treatments, even if the mean values for D plots never exceeded -1.0 MPa. Minimum  $\Psi_{pd}$  in the D treatment was similar in both years.

Leaf vapour pressure deficit (VPD) showed a bimodal pattern with a minimum in winter-spring and a maximum in summer, although July 2004 (4.8 kPa) was drier than July 2005 (3.5 kPa - Tab. 2).

Drier conditions during the summer had a strong effect on gas exchange activities. Significant reductions of stomatal conductance ( $g_s$ ) and maximum  $\text{CO}_2$  assimilation ( $A_{max}$ )

**Fig. 2** - Correlation of instantaneous water-use efficiency ( $WUE_{inst}$ ) and vapour pressure deficits (VPD) in water depleted (D) and watered (W) plots during the experiment.

were observed over the seasons, in response to changes in water availability (Tab. 2).  $g_s$  reached the maximum value ( $0.16 \text{ mol m}^{-2} \text{ s}^{-1}$ ) in spring 2005 when environmental conditions were most favourable, whilst the lowest minimum rate was recorded in July 2004 ( $0.04 \text{ mol m}^{-2} \text{ s}^{-1}$ ) under air and soil humidity stress. Despite the same  $\Psi_{pd}$ , the difference in  $g_s$  measured between July 2004 and 2005 was  $0.3 \text{ mol m}^{-2} \text{ s}^{-1}$ . This was likely due to differences in VPD recorded between the two dates.

Significant differences in  $A_{max}$  between the

D and W treatments were observed during the experiment, in particular during the summer drought. However,  $A_{max}$  values in D plots did not fall below 60% of those observed in the W treatment (Tab. 2); this was the consequence of not marked drought treatment imposed.

Because of parallel declines in  $g_s$  and  $A_{max}$ , computed intercellular  $\text{CO}_2$  ( $c_i$ ) concentration and instantaneous water-use efficiency ( $WUE_{inst}$ ) did not differ between treatments (Tab. 2). A slight increase in  $WUE_{inst}$  was observed in D plots during July 2004 and 2005. However,  $WUE_{inst}$  showed large fluctuations over the season, mainly related to changes in VPD (Fig. 2).

*$^{13}\text{C}/^{12}\text{C}$  and  $^{18}\text{O}/^{16}\text{O}$  isotope ratios in leaf organic matter*

The carbon isotope composition ( $\delta^{13}\text{C}$ ) was not affected by changes in SWC and VPD during the experiment (Tab. 2), with the exception of June 2005, when only slight and significant differences were shown between D and W plots. This result was consistent with our gas exchange findings, in which little or no changes in intercellular  $\text{CO}_2$  concentration ( $c_i$ ) and  $WUE_{inst}$  were found (Tab. 2). Furthermore,  $\delta^{13}\text{C}$  was negatively correlated with  $c_i/c_a$  as derived from leaf gas exchange assessments (Fig. 3). However, this result was significant only for treatment D ( $P < 0.05$ ) and D+W ( $P < 0.01$ ). A significant and positive relationship ( $r = 0.76$ ,  $P < 0.05$ ) was also found between  $\delta^{13}\text{C}$  and  $WUE_{inst}$  (data not shown).

In contrast,  $\delta^{18}\text{O}$  was found to be more sensitive to variations in soil water availability

**Fig. 3** - Correlation between leaf carbon isotope composition ( $\delta^{13}\text{C}$ ) and intercellular to ambient  $\text{CO}_2$  concentrations ( $c_i/c_a$ ) assessed by gas exchange in water depleted (D) and watered (W) plots during the summer in 2004 and 2005. Symbols represent the mean value  $\pm$  standard error for each date of measurement.

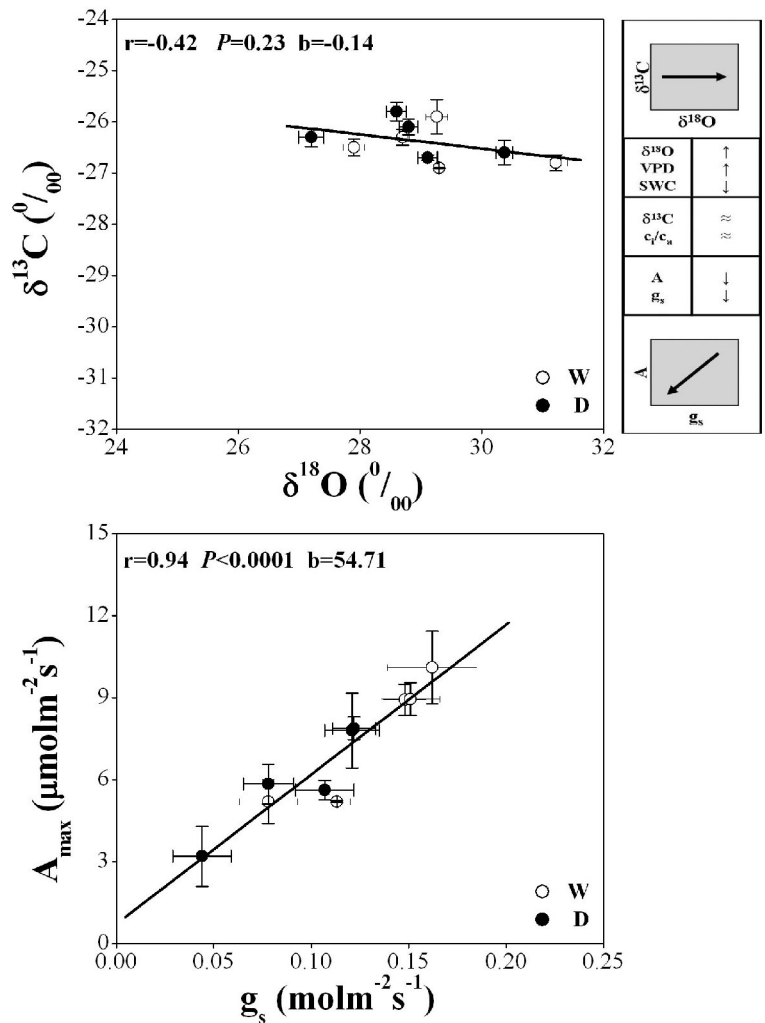

lity than  $\delta^{13}\text{C}$ . In fact,  $\delta^{18}\text{O}$  differed significantly between D and W plots in July 2004 and July/September 2005 (Tab. 2). A lack of difference in  $\delta^{18}\text{O}$  values recorded in June 2004 between D and W treatments suggests that full access to water for *A. unedo* trees did not differentiate  $g_s$  from the transpiration response.

$\delta^{18}\text{O}$  significantly increased in response to reduced stomatal aperture ( $P < 0.05$ ) and to the consequent leaf transpiration rate (Fig. 4). The correlation was not significant when the two treatments were considered separately, but they showed a parallel increase in  $\delta^{18}\text{O}$  with a reduction of  $g_s$ . Both had a similar slope from the linear fit. A significant and negative correlation ( $r = -0.67$ ;  $P < 0.05$ ) was observed between  $\delta^{18}\text{O}$  and  $\text{WUE}_{\text{inst}}$  (data not shown).

As a test of the dual isotope conceptual model,  $\delta^{13}\text{C}$  was found not significantly correlated with  $\delta^{18}\text{O}$  ( $r = 0.42$ ,  $P = 0.23$  - Fig. 5, top-left panel). The higher VPD during the period of leaf formation in 2005 led to a parallel increase in  $\delta^{18}\text{O}$  (more positive values) in both D and W plots. In contrast,  $\delta^{13}\text{C}$  was less sensitive to VPD changes, showing only

**Fig. 4** - Correlation between leaf oxygen isotope composition ( $\delta^{18}\text{O}$ ) and stomatal conductance ( $g_s$ ) assessed by gas exchange in water depleted (D) and watered (W) plots during the summer in 2004 and 2005. Symbols represent the mean value  $\pm$  standard error for each date of measurement.

**Fig. 5** - The  $\delta^{13}\text{C}$ - $\delta^{18}\text{O}$  relationship (top-left panel) in water depleted (D) and watered (W) plots during the summer in 2004 and 2005. The top right panel provides information derived from the  $\delta^{13}\text{C}$ - $\delta^{18}\text{O}$  relationship: this result is consistent with case c) in the Scheidegger model with the arrow pointing to right side; the model output of  $g_s$ - $A_{\text{max}}$  indicates a decrease of either  $g_s$  or  $A_{\text{max}}$ . The bottom panel shows the correlation between  $A_{\text{max}}$  and  $g_s$  from gas exchange measurements. Symbols represent the mean value  $\pm$  standard error for each date of measurement.

about 1.0‰ of variation. The direction of the arrow in the  $\delta^{13}\text{C}$ - $\delta^{18}\text{O}$  relationship matches scenarios C) and G), indicating that  $g_s$  and  $A_{\text{max}}$  were simultaneously affected by decreasing (scenario C) or increasing (scenario G).

## Discussion

Although the study period was slightly wetter than the area's long-term average (*i.e.*, 1095 mm in 2004 and 935 mm in 2005 - Tab. 2), the summer (June to August) was drier (*i.e.*, 90 mm in 2004 and 80 mm in 2005). Thus, the reduction in precipitation was 25% for the summer of 2004 and 33% for the summer of 2005 when compared to the long term average. This gives further evidence in predicted drier summers for Mediterranean regions (IPCC 2007). Moreover, the reduction of total precipitation (-20%) induced by the experimental manipulation exacerbated the summer drought.

As a result, the enhanced drought affected water and carbon relations, leading to reductions in maximum  $\text{CO}_2$  assimilation ( $A_{\text{max}}$ ) and stomatal conductance ( $g_s$ ) for *A. unedo* forests over the two monitored seasons. This result is in agreement with other studies on the same species (Castell et al. 1994, Gratani & Ghia 2002). Furthermore, variations in directly measured leaf physiological traits, *e.g.*, the intercellular to ambient  $\text{CO}_2$  ( $c_i/c_a$ ) ratio and  $g_s$ , were well reflected in the carbon ( $\delta^{13}\text{C}$ ) and oxygen ( $\delta^{18}\text{O}$ ) isotope signature measured in bulk leaf material. In particular, our data show that measurements of  $\delta^{13}\text{C}$  can be used to make time-integrated estimates of  $c_i/c_a$  at the tree or stand scale (Farquhar et al. 1989). In addition, the negative correlation between  $\delta^{18}\text{O}$  and  $g_s$  that we observed for D+W is consistent with other studies (Barbour & Farquhar 2000, Barbour et al. 2000, Sullivan & Welker 2007). This indicates that  $\delta^{18}\text{O}$  values reflect the signal of  $g_s$  variations under Mediterranean conditions. Although the correlation was not significant when the two treatments were considered separately, the similar slope and the parallel trend for the linear fit highlights the differences in  $g_s$  behaviour in response to different water availabilities. In fact, with  $\delta^{18}\text{O}$  equal,  $g_s$  was lower in D compared to W. This confirms stomatal control of transpiration, imposed by soil water restriction and coupled with high VPD conditions.

Thus, the reliable correlation observed between  $\delta^{18}\text{O}$  and  $g_s$  suggests that bulk leaf material was a suitable medium to infer the physiological performance of trees. This was previously observed by Sullivan & Welker (2007) and Barbour et al. (2000). While in other studies, the extraction of leaf cellulose was necessary because the  $\delta^{18}\text{O}$  determined in leaf matter was not correlated with  $g_s$  (Grams et al. 2007).

The combination of  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  in a

semi-quantitative model revealed qualitative variations of  $A_{\text{max}}$  and  $g_s$  across two different soil water regimes. Thus, in this investigation, the dual isotope model proposed by Scheidegger et al. (2000) was modified with the inclusion of SWC and rH (or VPD) as model inputs. Isotopic measurements on bulk leaf material showed an increase in  $\delta^{18}\text{O}$  and a slight variation in  $\delta^{13}\text{C}$ . Among the eight different  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  scenarios proposed in the model, our results matched scenarios C and G (see isotope theory). This means that  $c_i$  remained almost constant, that  $g_s$  and  $A_{\text{max}}$  were simultaneously affected, and that both increased (scenario G) or decreased (scenario C). Therefore, as air and soil water availability reduced in our experiment, we can assume that both  $g_s$  and  $A_{\text{max}}$  decreased (scenario C). The output of the model found a robust confirmation from our gas exchange measurements. In fact, we did not observe variation in  $c_i$  between D and W over the two years of the experiment. Furthermore, direct measurements of gas exchange revealed a reduction of both  $A_{\text{max}}$  and  $g_s$  with increasing water stress (from W to D). The information deduced from the carbon and oxygen stable isotopes reflects the long-term integrated information of  $A_{\text{max}}$  and  $g_s$  (because organic matter accumulates over some time) and are consistent with short-term gas exchange measurements on a different time scale.

The down regulation of  $g_s$  may have induced a parallel decrease in  $A_{\text{max}}$ , suggesting that stomata strongly limit carbon assimilation. However, a similar  $c_i$  found in this experiment in D and W plots, indicates that photosynthesis may have been down-regulated and that non-stomatal limitations may have played an important role (Lawlor & Cornic 2002). Through a study of quantitative limitation analysis carried out in July 2004 on the same experimental site, it was shown that non-stomatal limitations largely affected  $A_{\text{max}}$  (Grassi et al., unpublished data), accounting for 35% of total limitations (9% biochemical - carboxylation and electron transport rate - and 26% resistance to  $\text{CO}_2$  from intercellular spaces to carboxylation sites). Several studies have shown evidence that this is far from negligible, and it is often the most important factor under moderate water stress (*e.g.*, Loreto et al. 1992, Warren et al. 2004, Grassi & Magnani 2005).

Although the dual isotope approach has been shown to be a reliable tool to infer the relationship between  $g_s$  and  $A_{\text{max}}$ , it is not able to explain in details the underlying mechanism involved. In fact, under Mediterranean conditions, it is often necessary to assess the contribution of stomatal and non-stomatal limitations in driving changes in  $A_{\text{max}}$  and  $g_s$ , and their weight in this ratio that, in turn, affects the WUE.

As a result of the parallel decrease in  $g_s$  and  $A_{\text{max}}$ , we observed little or no differences in either  $\text{WUE}_{\text{inst}}$  and integrated WUE as assessed by  $\delta^{13}\text{C}$ . This result contrasts with most findings in Mediterranean areas, where a significant increase in WUE has been found (Ogaya & Peñuelas 2003, Lloret et al. 2004, etc.). These results derive from a more intense stomatal control of water loss than inhibition of photosynthesis.

The large fluctuations in  $\text{WUE}_{\text{inst}}$  over the two seasons appear to be mainly related to changes in VPD. Thus, VPD is considered an important parameter in driving gas exchanges in Mediterranean environment (Martínez-Vilalta et al. 2003) and in influencing the productivity of forest ecosystems (Law et al. 2001).

## Conclusions

The combination of  $\delta^{13}\text{C}$ - $\delta^{18}\text{O}$ , in a semi-quantitative conceptual model, proved to be a valid tool for investigating the time integrated  $g_s$ - $A_{\text{max}}$  relationship under Mediterranean conditions. In fact, a constant  $\delta^{13}\text{C}$  and an increase of  $\delta^{18}\text{O}$  isotopes in response to reduced air and soil water availability were consistent with a parallel decline of either  $g_s$  and  $A_{\text{max}}$ , as assessed by gas exchange. The good correlations found between  $\delta^{13}\text{C}$  and  $c_i$  or between  $\delta^{18}\text{O}$  and  $g_s$  confirm this result. Furthermore, either instantaneous (from gas exchanges) and integrated WUE (from  $\delta^{13}\text{C}$  isotopes) data are in agreement in showing that, as a consequence of a parallel decrease of either  $g_s$  and  $A_{\text{max}}$ , soil water restriction had no or slight influence on WUE. VPD was shown to have a larger impact on WUE than SWC. Such a response should result in a negative feature under climate change scenarios that may further reduce the carbon sequestration and the productivity of Mediterranean forests.

## Acknowledgments

This research was supported by the EU Project n. EKV2-CT-2002-00158 MIND "Mediterranean terrestrial ecosystem and Increasing Drought" and the MIUR-PRIN Project prot. 003073315\_003 "Drought and Mediterranean forests: stomatal mechanisms in the regulation of plant gas exchanges". The authors would like to thank the coordinator of the MIND project, Dr. Franco Miglietta, and the Principal Investigator of the research group, Prof. Marco Borghetti. The authors also express their gratitude to Raddi S, Nolè A, Lapolla A, Anichini M, Cantoni L and Vicinelli E for helpful support in field measurements.
