Historical and contemporary forest ecosystem changes in the Beskid Mountains (southern Poland) between 1848 and 2014

Michal Sobala, Oimahmad Rahmonov, Urszula Myga-Piatek

Landscape changes in the Carpathians are related to centuries of human activity, which can be regarded as the key component of global change. Changes in mountainous regions are mainly caused by agriculture, urbanization, forest cutting for production and land abandonment. This paper aimed to assess the impact of natural and historical-cultural factors on forest ecosystem transformations occurred in the period 1848-2014 in two small areas (about 45 km²) on the Beskid Mountains (southern Poland). The comparison of historical and current maps, along with the application of GIS and field verification, allowed a full interpretation of changes in land use in the studied areas. A decrease of 58.0% in non-forest areas was observed in the considered period, while the forested area grew systematically by 28.3% and the forest-field boundary lowered in altitude. Current forest ecosystems are distributed as a mosaic and mainly consist of Abieti-Piceetum montanum, with logged sites taking up large areas. Forest ecosystems include valuable semi-natural meadows such as Gladioleo-Agrostietum, Hieracio-Nardetum, Arrhenatheretum medioeuropaeum, Cirsietum rivularelis or Juncetum effusi, whose extension is reducing and fragmentation increasing due to the recolonization of forest tree species after abandonment. We concluded that trends in land use in the Carpathians were mainly determined by non-environmental factors related to the development of farming-pasturing and forest management. The applied approach could be extended to other regions in the Carpathians which were subject to analogous historical-cultural influences. Moreover, our results allow for a comparison with other regions which are subject to similar impacts of natural processes, but to different impact of historical and cultural processes.

Introduction
Landscape is subject to increasing anthropogenic transformation in land use or land cover, which can be interpreted both locally and globally (Antrop 2005, Plit 2014). Analysis and evaluation of the rate of these changes are feasible when reliable cartographic resources recording land use and types of land cover through time are available. Beside the educational value, the interpretation of these resources is also important from the economic point of view, as it makes possible the optimization of contemporary economic processes (Pleninger et al. 2016). Analysis of changes in land use over time also enables to assess the impact of natural factors – both positive (fertile soils, small height differences, mild climate, etc.) and negative (floodings, mass-movements, volcanic eruptions, pest gradation, natural fires, etc.) on the landscape.

Landscape diversification has increased in the past decades, often resulting in disturbances to the functioning of ecosystems (Goldewijk 2001, Hansen et al. 2016). Typological diversification of landscapes has been occurring over time because of human economic activities through centuries, determining the development of specific anthropogenic ecological systems within various landscape zones (Farina 2000, Vold & Buffett 2008, Myga-Piatek 2012, Munteanu et al. 2014, Ellis 2015, Pienkowski 2015). Such activities include urbanization, intensification of agriculture, forest cutting for production and/or land abandonment (Pleninger et al. 2016), whose impact varies regionally depending on local socio-economic and natural conditions (Pinto-Correia & Kristensen 2013).

The main types of landscape change over Europe and their driving factors have been widely discussed in a recent review (Plieninger et al. 2016). Similar analyses have been carried out in the Carpathians (Griffiths et al. 2013, Munteanu et al. 2014), and in areas adjacent to the Beskid Mountains in Poland (Boltzian et al. 2016), mainly focused on changes in forest areas and the farming use of land. Changes in the forest cover over the past 180 years have been examined in western and northern Carpathians (Kozak 2003, 2010, Kozak et al. 2007).

Carpathian mountain range covers more than 190,000 km² throughout eastern Eu-
rope, extending for 1300 km in length and 120–350 km in width, and includes a unique combination of ecosystems. The Carpathians run through as many as 7 countries: Slovakia (about 71% of its area), Romania (ca. 47%), Czechia (ca. 8%), Hungary (ca. 8%), Poland (over 6%), Ukraine, Austria and Serbia. As a consequence, different models of land management, determined both historically and culturally, have appeared and still exist in different parts of the Carpathians (Munteanu et al. 2014), resulting in regional differences in changes in ecosystems and landscapes.

Changes in specific landscape elements (forests, abandoned land, meadows, hydrographic networks, cultural elements) have been analysed throughout the Carpathian range with different degrees of detail (Kaim 2009, Ostafin 2009, Kozak 2010). However, most studies were large-scale investigations based on either cartographic resources or satellite- and aerial imagery aimed at quantifying changes in forest cover (Kozak et al. 2007, Munteanu et al. 2014). Contrastingly, few studies have focused on changes in species composition of forests in the Silesian and Zywiec Beskid Mountains, which are part of the Polish Carpathians.

The aim of this paper was to determine the impact of natural and historical-cultural factors on forest ecosystem transformations in the Silesian and Zywiec Beskid Mountains over the period 1848–2014. An accurate assessment of landscape changes was carried out in two small mountainous areas (<100 km²) which had been exploited by man for centuries. A detailed verification in the field of the results obtained from cartographic analyses allowed to recognize the transformation of fir-beech phytocenoses and the succession in managed spruce forests in the light of natural and anthropogenic factors.

**Materials and methods**

**Description of the study area**

The Beskid range (Western Carpathians) stretches for about 600 km from the Bečva River in the west to the Cheremosh River in the east, and reaches a width of about 50–70 km. We selected two research areas (the Barania Góra Range and Racza Range, each covering about 45 km²) situated in the Western Beskids (49°32′–45°N, 18°26′–51°E – Fig. 1), both characterized by medium- and low mountain relief with steep slopes (mean elevation > 800 m a.s.l.). The base- ment is made from formations of the Gó- dula Nappe and the Magura Nappe of the Carpathian Flysch Belt. The areas span over three vertical climatic zones, namely, moderate warm (with mean temperature > 6 °C), moderate cool (4–6 °C) and cool (< 4 °C). Precipitation on the highest ridges (Skrzyczne or Wielka Racza) reaches 1300 mm year⁻¹.

The natural conditions of the area are suitable to forests and meadows/grasslands, whereas current land use reflects the socio-political and economic conditions in the late 19th century, when the Beskid region was heavily populated and large areas were deforested for agricultural use, despite unfavourable topographic-, soil- and climatic conditions (Sobala 2012a). This has generated the current traditional landscape typical of the Beskid region, with buildings situated in the valley bottom on lower river terraces with accompanying woods and shrubs, and cropfields perpendicular to the valley bottom divided by clearly marked baulks, which reach up to the edge of the forest on mountain ridges. Numerous clearings with farmsteads are located in flat areas of the forest, and mountain ridges includes pasture grounds which recently decreased in area due to the abandonment of breeding farm management.

**Cartographic analysis**

For the analysis of changes in landscape over time, only maps based on direct field mapping were selected in this study. We decided to select map series with similar scales and objectives; however, we encountered serious difficulties to match such criteria. Therefore, only six of the seven maps acquired were used in this study, as reported in Tab. 1.

All the historical maps were georeferenced in two steps, which consisted in: (i) calculating the transformation matrix; (ii) carrying out proper geometric transformation and interpolation resampling of a distorted image to a new raster of regular size (i.e., the so-called “rubbersheeting”). Such two-step process allowed a higher georeferencing accuracy, which ensures the quality of results obtained and increases the

confidence in the conclusions. In each case, georeferencing was specifically adjusted to the quality and type of data, so as to achieve the best possible results for each series.

Austrian cadastral maps were overlaid onto a grid with a size corresponding to the map frame size using affine transformation and the coordinates of the frame corners. Rectification was then carried out and its precision verified by estimating the root-mean-square error (RMSE), which was < 4.91 m for each map sheet.

The Specialkarte der Österreichisch-Ungarischen Monarchie was georeferenced only by means of control points of the reference layer using the affine transformation. This kind of georeferencing of a single map sheet gives better results than that based on fitting the corners in the millimeter-mesh grid (Affek 2013).

The military maps were georeferenced by overlaying the corner points of the raster image onto the grid with a size corresponding to the map frame size using affine transformation. Rectification was then carried out and the image was adjusted to the reference layer using control points.

For all maps, historical local reference systems were transformed into the contemporary global system. This step involved the application of a simplified Helmert transformation with three parameters (dx, dy, dz) of the shift in the coordinate system origin using the inverse Molodensky formulas (Sobala 2012a).

The processed cartographic materials underwent screen digitization using the snapping method. Errors are usually generated during this operation, e.g., duplicating arcs, floating- or short lines, overlapping lines, overshoots and undershoots, unclosed- and weird polygons (Maras et al. 2010). A topology construction tool was used to detect and eliminate these errors.

Screen digitization was combined with the creation of a database of land-use and land-cover forms. By aggregating the data included in each series of maps, land-cover maps were developed where forest and non-forest areas were clearly distinguishable. In both cases, the road network and the hydrographic network were attached to the adjoining polygons, as the boundaries ran along roads and watercourses.

As a result of the procedures described above, vector maps were created which allowed spatial analyses to be carried out. The V_LATE add-on of the package ArcGIS® ver. 10.2.2 was used, which allowed to calculate landscape metrics describing land cover and the forest-field boundary in each time section. Indicators of changes in forest and non-forest cover in each time section were calculated by the following parameters:

- Changes in Forest Area ($CF = FA_{\text{new}} - FA_{\text{old}}$);
- Changes in Non-forest Area ($CN = NA_{\text{new}} - NA_{\text{old}}$);
- Changes in Forest Area in relation to Total Area ($CFA = 100 \cdot \frac{FA_{\text{new}} - FA_{\text{old}}}{NA_{\text{old}}}$);
- Changes in Non-forest Area in relation to Total Area ($CNA = 100 \cdot \frac{NA_{\text{new}} - NA_{\text{old}}}{NA_{\text{old}}}$);
- Percentage changes in Forest Area between time section $t$ and $t+1$ ($CPF = 100 \cdot \frac{FA_{t+1} - FA_{t}}{FA_{t}}$);
- Percentage changes in Non-forest Area between time section $t$ and $t+1$ ($CPN = 100 \cdot \frac{NA_{t+1} - NA_{t}}{NA_{t}}$).

### Analysis of vegetation changes

The analysis of changes in forest and non-forest areas was conducted for the years 1848–2014 on the basis of the available cartographic resources (Tab. 1). The maps differed with regard to land-cover forms (including vegetation types). Only some maps contained information on forest types, which were classified as deciduous or coniferous. Consequently, it was not possible to compare vegetation changes (in terms of plant communities and associations) for all time intervals. Therefore, vegetation changes over time were inferred by comparing the current vegetation map based on field mapping performed with an itinerary method (Sadikov 2012) and the map of potential natural vegetation of Poland (Małuszkiwicz et al. 1995). The latter map was used as reference for determining changes in the forest associations in the analysed areas. It was the only applicable method due to lack of information on past forest types in the study area.

### Results

Changes in forest and non-forest cover in years 1848–2014

In both study areas, the forest cover grew systematically at the expense of non-forest areas in the period 1848–2014 due to the abandonment of agriculture (Tab. 2, Fig. 2, Fig. 3). The increase in forest cover in the Racza Range was higher than...
that observed in the Barania Góra Range (16.7 % vs. 11.8 %, respectively). The greatest changes in the Barania Góra Range, affecting 6.8 % of the examined region, took place between 1933 and 1960, whereas in the Racza Range forest cover changed continuously since 1933 and involve 13.9 % of the investigated area.

Throughout 1848-2014, the number of non-forest patches was higher than that of forest patches, with different trends through time in the two studied regions. In the Barania Góra Range, we observed an increase in the largest forest patches over the considered period, whereas in the Racza Range it decreased until 1933 and then started to increase.

Changes in the forest-field boundary
In both the Barania Góra Range and the Racza Range, the length of the forest-field boundary initially decreased (by 39.4 km and 45.4 km, respectively), and then increased (by 13.3 and 67.3 km) before decreasing again (by 15.4 and 68.2 km). The numbers of boundaries and patches reveal a similar tendency. In both study areas the forest-field boundary was observed to progressively decrease in elevation (Fig. 4). To illustrate the effect of the map scales on...
the results, data on the number of borders and their minimum lengths are given in Tab. 4. The main trends of changes in the length and numbers of forest boundaries and patches are shown in Tab. 5.

Vegetation changes

The study area is situated within the foothills and the lower forest zone (lower subalpine zone) which is the optimum (climax) for *Fagus sylvatica* and *Abies alba*, the main species characterizing beech and fir-beech forests. The plant communities typical of these layers are: *Alnetum incanae*, *Carici remotae-Fraxinetum*, *Dentario glandulosae-Fagetum*, *Luzulo nemorosae-Fagetum*, *Sorbo-Aceretum carpaticum*, *Abieti-Piceetum montanum* and *Plagiothecio-Piceetum tatricum*.

The comparison of potential natural vegetation with current vegetation distribution revealed large changes in both species composition and the distribution of forest associations in the two study area (Fig. 5).

The grey alder association *Alnetum incanae* can only be found at sites in alluvial river valleys on mountain alluvial soils. The main tree species is *Alnus incana*; other species are *Fraxinus excelsior*, *Acer pseudoplatanus*, *Picea abies*, *Salix fragilis* and *Salix alba*. Small areas in river valleys are occupied by ash carrs *Carici remotae-Fraxinetum*, where the tree layer is mainly represented by *Fraxinus excelsior* and *Alnus glutinosa* with the addition of *Fagus sylvatica*, *Acer pseudoplatanus*, *Picea excelsa*, *Alnus incana*, *Quercus robur*, *Salix alba* and *Salix fragilis*.

The most extended floral habitat in the Silesian and Zywiec Beskids is the fertile Carpathian beech wood *Dentario glandulosae-Fagetum*. The largest and best preserved parts of this association remained in the Racza Range. The dominant association *Dentario glandulosae-Fagetum typicum*

is composed of *Fagus sylvatica*, *Acer pseudoplatanus*, *Fraxinus excelsior*, *Abies alba* and *Picea abies*. Another frequently occurring association is acid beech wood *Luzulo nemoroseae-Fagetum*, which is almost solely composed of *Fagus sylvatica*, with a small proportion of *Abies alba*, *Acer pseudoplatanus*, *Fraxinus excelsior*, *Picea abies*, *Betula pendula* and *Quercus robur*.

The Carpathian sycamore *Sorbo-Aceretum carpinetum*, composed of *Sorbus aucuparia*, *Acer pseudoplatanus*, and *Fagus sylvatica* with a proportion of *Picea abies*, occurs sporadically, with trees often low and twisted.

Near-top parts of slopes are mainly occupied by the low montane fir-spruce wood *Abieti-Piceetum montanum*. The tree layer is composed of *Picea abies*, *Abies alba*, *Fagus sylvatica*, *Sorbus aucuparia*; *Acer pseudoplatanus* and *Betula pendula* also occur sporadically.

The West-Carpathian spruce forest association *Plagiothecio-Piceetum tatricum* is not commonly found due to the altitude of the study area. Small fragments can be found in higher parts of the hills and on hilltops, due to planned forest management in the early 21st century (Fig. 5).

**Discussion**

**Map types and interpretation of results**

The maps used in this study differ both in terms of scale (from 1:2,880 of the Austrian cadastral maps to 1:100,000 of the WiG military maps), their use (military or administrative purposes) and map projection. Therefore, results based on these maps need careful interpretation and verification using other data sources. Furthermore, the results could be affected by errors occurring at each stage of the creation of a digital map; particularly, georeferencing greatly affects the quality of results. Furthermore, the information value of map data is lower compared to direct source data, having a lower precision and accuracy. Being aware of the limitations of maps is the basis for drawing correct conclusions (Pilt 2006).

The main results of this study, obtained by applying the most appropriate methods of analysis of cartographic historical data, can be summarized as follows:

- The dynamics of changes in land cover in two areas of the Beskid mountains were assessed by comparing the distribution and extension of different land cover types on maps from different time intervals. Although the results obtained should not be treated as absolute (see the above considerations), it was still possible to assess the trends related to changes in land cover in the study areas.
- The course of the forest-field boundary was analyzed with great care, as its length and density are particularly dependent on the map scale. The geometric simple choropleth method was used for this purpose. Applying a definite size of the basic field in relation to some generalization of the map contents allows excessive precision to be avoided. The size of the basic field was determined by the geometric method.
- The detection of changes in forest ecosystems based on cartographic materials was feasible only in terms of tracking changes in spatial distribution of forest/non-forest areas. A detailed analysis of changes in forest ecosystems in terms of transformations of particular forest associations (their spatial distribution and composition in species) is only possible based on field research. The comparison of current distribution of particular forest associations with the potential vegetation has provided important hints for assessing the impact of cultural-historical factors on changes in forest ecosystems.
Changes in land use between 1848-2014

Forest landscapes in the Silesian- and Żywiec Beskids are located at higher elevations (forest belt) and include non-forest glades and pastures. On the other hand, agricultural landscapes are situated at lower elevations (foothill belt), and include forest patches, like small enclaves next to water courses or on steeper slopes. Our results highlight that the forest belt increased in the period 1848-2014 at the expense of the foothill belt. As in other parts of the Carpathians, changes in the forest area were closely related to changes in the range of areas used for agricultural activities (Farina 2000, Munteanu et al. 2014, Boltiziar et al. 2016).

Our results on the length of the forest-field boundary should not be treated as actual absolute values. However, they can be useful to assess the importance of the various spatial processes involved in the transformation of the landscape (Forman 1995).

In general, we observed a decrease in length of the forest-field boundary through time, and a reduction in number of boundaries and patches. This could have been caused by the shrinkage of non-forest patches rather than their fragmentation. When fragmentation of patches becomes dominant over their shrinkage, the number and length of boundaries and the number of patches started to increase (Forman 1995).

The trends in land use in the two studied areas were mainly determined by non-environmental factors. Land use in 1848 was the result of the so-called “land hunger”. Overpopulation and poor economic conditions forced to set arable lands at higher elevations and sloping hills, although most sites were unsuitable for crops. As a result, land use was far from sustainable in the mid-19th century and the pressure on the environment was high. At that time, the landscape was highly diversified, as occurring in other European countries (Antrop 2005).

Due to slightly different starting natural conditions, the land use structure was closer to the optimum in the Racza Range than in the Barania Góra Range, being the latter lesser managed than the former. This reflects the harsher geomorphological conformation of the Racza Range, which still represents a barrier for transports (Sobala 2012b).

Starting from the late 19th century, intensified forest management and access limitations to forests contributed to a progressive reduction of the traditional meadow-pasture management. Furthermore, increased acquisition of land for residential building and crops caused a reduction in the area for pasture. Additionally, the outflow of people towards the growing industrial centers and high market competition for sheep products contributed to the abandonment of pasture management in the higher parts of the mountains (Gerard et al. 2006, Kuenmerle et al. 2007). As a consequence, clearings and pastures were overgrown with forest and their size decreased. Nevertheless, grazing continued in some clearings and pastures until the 1990s. The gradual disappearance of seasonal shepherding resulted in secondary succession of forest to take place onto unused pastures and clearings; some of these are now completely forested (Fig. 6a).

The decrease in the non-forest area is still ongoing on the entire range of the Polish Carpathians as a result of political changes and socio-economic transformation, e.g., the ending of subsidies for mountain farms, the 1988 act on business activities which fostered non-agricultural activities, the decrease in demand for sheep products, increased production costs and the lower profitability of farming (Müller et al. 2013, Griffiths et al. 2014). In some cases, owners intentionally planted trees on some parts of unused clearings. Since the early 20th century, programs of active nature protection using sheep grazing have been implemented in selected clearings and pastures, thus contributing to slow down secondary forest succession (Fig. 6b – Sobala 2014). Such actions have been successfully implemented in many other mountain regions of Europe (Finck et al. 2002). After Poland’s accession to the European Union, a new agricultural policy and an increased awareness of the loss of valuable plant communities in mountain areas led to more appropriate management of those regions.

Forest clearings and biodiversity

Changes in land cover in the Barania Góra and Racza Ranges since 1848 have contributed to renaturalization of formerly cultivated forest clearings through the reclamation of forest tree species. On the other hand, the ecological consequences of such changes involve a decrease in biodiversity, a larger fragmentation of rare habitats, the weakening of soil denudation and microclimatic changes (Ostatin 2009, Munteanu et al. 2014), as well as a decreased scenic value (Pilt & Myga-Platek 2014, Pilt & Myga-Platek 2016) due to the homogenization of the landscape (Farina 2000, Déjeant-Pons 2006).

The reclamation by forest tree species of abandoned pastures and meadows poses a serious threat to such communities in terms of species and ecosystem biodiversity (Towpaz & Zemanek 1995), including a very large group of rare and unique mountain species protected by law, not only in Poland. Plant communities found in the studied area are relevant at the European context and would deserve protection as Natura 2000 areas. Such communities include Hieracio-Nardetum, Carline-Dianthetum, Cirsietum rivularis, Adenostylion aliariorum, Arthrenchetum elatisior and Gladiolus-Argostietum caninae.

Our results indicate that plant communities in the study areas have been significantly transformed by man and do not reflect the potential natural vegetation at present. Starting from the late 15th century, forests were thinned (by burning or cutting down) in order to obtain land for grazing and agriculture (Sobala 2016). As a result, the range of Alnetum incanae and Carici nemorosae-Fraxinetum decreased in river valleys. Moreover, the field-forest boundary moved upwards, shrinking the range of Dentario glandulosa-Fagetum and Luzulo nemorosae-Fagetum, which were replaced by ploughland at lower locations and by meadows and pastures at higher altitudes. The history of vegetation in the Beskids can only be revealed indirectly based on paleobotanical research. The dominance of Fagus sylvatica, Abies alba, Alnus incana, Fraxinus excelsior and Picea abies is confirmed by paleobotanical studies conducted in numerous locations in the Polish Carpathians (Towpaz & Zemanek 1995, Wilczek 1995). Forests in Silesian and Żywiec Beskids probably share a common history with other Carpathian forests. Beech and fir colonized the current forest areas of the Beskids after the spruce, which was the dominant species until ca. 2000 BC, and by 300 AD they occupied the largest habitat area. Until the 15th century the Beskids were covered by natural mixed (mainly fir-
beech) forests, with increasing proportion of spruce with altitude (Wilczek 1995). Only small patches, such as steep slopes and narrow belts on river bank gravels, were not covered by forest. Following the intro-
duction of grazing in the late 15th century pastures were created within the Abieti-Betulae montanum, and forests surrounding villages were used for tree logging and branch litter collection. However, it was in the 19th century, when forest management was introduced, that large transformations of forests took place (Brodka 1956, Vera 2007). The shift toward intensive forest thinning for indus-
trial needs changed the spatial distribution of forest communities and their species composition. As a result, lower subalpine beech-fir tree stands were destroyed and replaced with spruce plantations (So-
bal a 2012c), whereas the area of Abieti-Betulae montanum increased at higher alti-
uitudes. Most patches of this plant community are of secondary origin and have poor species composition, e.g., the share of Abies alba is much lower in the study area compared to patches in other parts of the Carpathians (Wilczek 1995). At the begin-
ning of the 21st century, forests in large areas were degraded to such an extent (be-
cause of biotic, abiotic and anthropogenic factors) that tree clearance appeared to be necessary (Fig. 6c – Malek et al. 2010). At present, these regions are undergoing the regeneration of forest community, accord-
ing to their habitats (Farina 2000, Déjeant-Pons 2006, Hlasy & Sitkova 2010).

Changes in land use due to deforestation and subsequent reforestation are common to many mountain regions, especially in de-
veloped countries, and are called “forest transition” (Mather 1992, Rudel et al. 2005, Meyfroidt & Lambin 2011). Reforestation started in Western Europe in the early 19th century and developed after World War II (Mayher 2001). In Central and Eastern Eu-
rope, the increase in forest areas was mainly related to socio-economic transforma-
tions in the countries of the former Eastern Bloc in the late 1990s (Gellrich et al. 2007, Bíloň & Jeleček 2009, Griffiths et al. 2015). However, in the Western Beskids deforestation took place later due to the shortage of land resources, and reforesta-
tion started in the late 19th century, when forest management intensified and less suitable arable lands were abandoned (Ver-
burg et al. 2010, Munteanu et al. 2014).

Conclusions
This study identified the following effects of land use and landscape changes in the past 200 years:

- The forested area in the Racza and Bara-
nia góra Ranges grew systematically be-
tween 1848-2014 at the expense of non-
forest areas, where farming was aban-
donated. The number of non-forest patches was higher than that of forest patches. Changes in the forest areas in this part of the Carpathians have continued since the early 20th century.

- The area of clearings and pastures de-
creased significantly because of intensi-
ﬁed forest management, the use of land for residential buildings and crops, and the natural recolonization by forest tree species. All these factors contributed to the gradual decline of traditional meadow-pasture management.

- Changes in the forest/non-forest cover over time were accompanied by a de-
crease/increase in the length of the for-
est-field boundary and its lowering rela-
tive to altitude. The attrition of the boundary progressed from the highest levels of the mountains to areas close to permanent rural buildings.

- Analysis of cartographic resources and historical scientiﬁc papers, along with ﬁeld veriﬁcation, enabled a full interpre-
tation of changes in land use in the chosen time interval. The study of historical maps combined with contemporary field data has potential for monitoring further landscape dynamics.

The approach applied in this study could be easily extended to other Carpathian re-
regions subject to analogous historical-cultural inﬂuences (similar type of settlement, model of land use, policy regarding agriculture and environment, etc.). Moreover, the results obtained allow the comparison with other regions in Europe subject to a similar impact of natural processes, but a different impact of historical and cultural processes.
