

Pilot-scale drying of southern pine (*Pinus* spp.) lumber in a heated tube dryer

Rubin Shmulsky,
Laya Khademibami,
Fatemeh Rezaei

Drying is essential for preserving the strength and durability of wood and wood products. This study aimed to evaluate the performance of a pilot-scale tube-type lumber dryer. Solid sawn rough green southern yellow pine (*Pinus* spp.) specimens, approximately 2 inches thick by 6 inches wide, and 12 feet long ($\approx 5\text{ cm} \times 15\text{ cm} \times 3.66\text{ m}$), were inserted into heated tubes for drying. The pilot scale dryer had four sealed (but open at each end) steel heated tubes, and each tube was sized to hold four specimens. Each tube was 36 ft ($\approx 11\text{ m}$) long. The temperature of the tube was controlled by rapidly circulating hot air about the tubes' exterior. Each tube had 3 temperature zones, and each temperature zone was controlled individually. Each lumber specimen was inserted into zone 1 and dried for a specified amount of time, and then advanced to zone 2 and zone 3. The delta moisture content of dried specimen was calculated based on the initial and final weight and final moisture content. The results showed that the delta moisture content was greatest at 425-425-400 °F ($\approx 218\text{-}218\text{-}204\text{ °C}$) and lowest at 400-400-350 °F ($\approx 204\text{-}204\text{-}177\text{ °C}$). Greater weight-loss rates were observed in the dried lumbers within the temperature range of 375-375-375 °F ($\approx 191\text{-}191\text{-}191\text{ °C}$). In summary, this device rapidly dried the lumber, and moisture content standard deviations were relatively high.

Introduction

As a biological and natural material, wood changes in response to its surrounding environment. It can be affected by weather factors such as air humidity, precipitation, biological issues, radiation (UV, IR), etc. Drying is an indispensable aspect within the realm of wood processing, leading to significant enhancements in the material's physical characteristics, mechanical properties, dimensional stability, and its suitability for coatings (Liu et al. 2019, 2021, Liu & Hu 2021, Wan et al. 2021). Lumber with a moisture content (MC) below 20% is highly resistant to fungal issues like stain, decay, and mold. Dry lumber is stiffer than wet, thereby enhancing its structural performance. Fasteners perform better in dry as compared to wet lumber. Products from properly dried lumber experience minimal shrinkage and develop better gluing, ma-

chining, and finishing performance. Additionally, lumber intended for treatment with fire retardants or preservatives should be partially dried to facilitate chemical penetration (Denig et al. 2000).

Energy is essential to evaporate moisture during wood drying. Free water evaporates readily, while removing bound water requires increasing energy as MC decreases (Penvern et al. 2020). Proper temperature control in drying is crucial. Higher temperatures hasten drying but prolonged exposure to wood, and cause defects like checking, cracking, and warping, while also impacting its color and deterring pests (Oltean et al. 2007). Proper humidity control is essential for quality drying, with lower relative humidity accelerating the process but potentially causing issues like cracking, splits, and honeycomb in some cases (Sundararaj 2022, Elustondo et al. 2023). Balanc-

ing time, temperature, and relative humidity to achieve the desired MC and quality can be challenging.

Various wood drying methods exist, including shed air drying, forced air shed drying, warehouse pre-drying, low-temperature kiln drying, platen vacuum drying, dehumidification drying, and conventional steam-heated kiln drying (Denig et al. 2000). Platen drying of lumber is a means by which wood is rapidly dried *via* conductive heat. There, smooth heated platens directly contact the wood surfaces and thus transfer energy to the wood directly. The selection of each method hinges on factors like cost, equipment availability, wood properties, and environmental factors.

Southern yellow pine (*Pinus* spp.) lumber and plywood are commonly used in construction due to its notable strength among softwood species (Wang et al. 2018). It is distinguished by its significant resin canals and distinct abrupt growth rings, which feature wide and prominent latewood bands. These wide latewood bands can slow the drying process and induce internal stresses due to varying shrinkage behaviors. The abrupt transition from earlywood to latewood can create stress concentrations within the wood, making it more susceptible to internal stresses and defects such as checking and splitting. The latewood percentage varies from approximately 25% to 60%. In younger and more rapidly grown plantation trees,

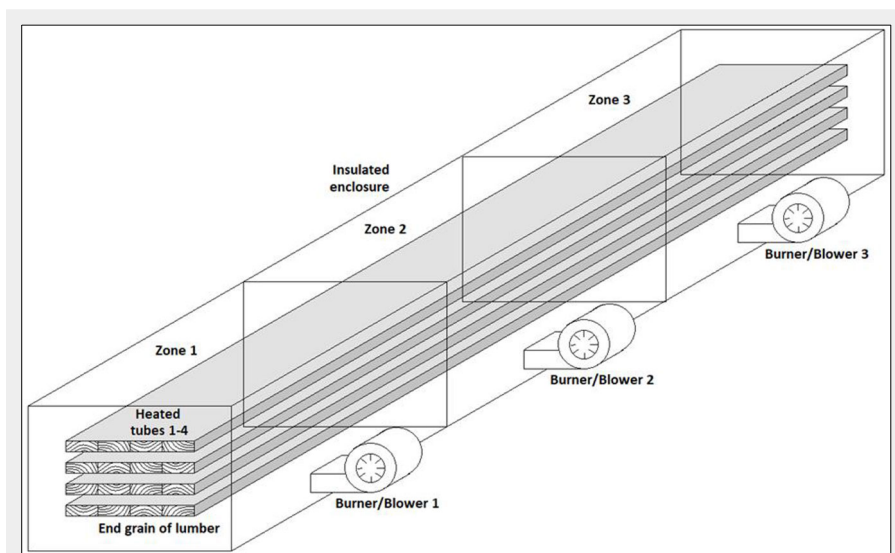

Fig. 1 - Schematic of the 3-zone tube dryer.

lead to technology adoption. It is crucial to emphasize that optimizing the drying process for various batches of sawn lumber is essential. This stems from differences in initial moisture content, wood densities, anatomical structures across wood species, and variations in lumber sizes. This study sought to design, construct, and test a gas-fired pilot-scale tube-type dryer. It also investigated the weight loss, and ΔMC , of pine lumber when exposed to different temperature zones and differing residence times.

Material and methods

Wood

Two inches by 6 inches by 12 feet ($t \times w \times l$) rough southern yellow pine (*Pinus* spp.) specimens were used ($\approx 5 \text{ cm} \times 15 \text{ cm} \times 3.65 \text{ m}$). The assessed mean density of the material was 38 lb ft^{-3} ($\approx 609 \text{ kg m}^{-3}$). Lumber was procured from a regional production sawmill in Northeastern Mississippi. Its annual production was on the order of 150 million board feet per year (≈ 0.354 million cubic meters). Rough green freshly sawn lumber, from freshly felled logs was taken from the mill and brought to the laboratory at Mississippi State University for experimentation. Once the drying was completed, the rough (non-surfaced) dry lumber was returned to the mill for further processing and sale.

Heated tube drying process

The heated tube dryer (HTD) consisted of four heated solid-wall rectangular tubes is shown in Fig. 1. The inside dimensions of each tube were fixed at 2-inches high by 24-inch wide by 36-ft long ($\approx 5 \text{ cm} \times 61 \text{ cm} \times 11 \text{ m}$). Each tube was constructed of quarter-inch ($\approx 0.635 \text{ cm}$) thick plate steel. Each end of each tube was open. As such the only avenue for moisture vapor to exit the dryer was via the ends of the tubes. Vapor pressure provided the sole driving force for moisture removal.

Tubes were supported by a rigid frame such that they remained straight and true for the entire length. In contrast to press drying, this process had no moving platens. As each specimen shrank during drying, contact pressure between the wood and the platens decreased to nearly zero. It was recognized that this system was imperfect with respect to conductive heating, however it had the advantages of ruggedness, simplicity, and continuous process flow.

Immediately surrounding the tubes was a heated and insulated chamber. Heat was provided via natural gas burners. As such the outside of the tubes was directly heated via the combustion gases. Burners were thermostatically controlled to approximately plus or minus 35°F ($\approx 2^\circ \text{C}$). Along the 36-ft ($\approx 11 \text{ m}$) long dryer there were three natural gas burners and three walled-off zones. As such, some amount of zone temperature control (three zones)

the latewood percentage is generally lower in this range. The latewood percentage is often at the higher end of this range in older, more mature, slower-grown trees. Based on the author's experience, the initial moisture content of freshly sawn southern pine lumber is approximately 110%, on a dry basis. The specific gravity of pine varies from approximately 0.50 to 0.60.

With respect to structural lumber, the southern pine group consists of four *Pinus*

species varieties: *P. echinata* (shortleaf), *P. elliottii* (slash), *P. palustris* (longleaf), and *P. taeda* (loblolly). Once manufactured, the lumber from these species is indistinguishable. Of these, the vast majority of lumber comes from *Pinus taeda*. Based on the forest resource from which this lumber was manufactured, it is assumed that all material used in this study was *Pinus taeda*.

Controlling the drying process is critical to minimize these issues (Bond & Rappold 2019). Southern pine is, however, highly permeable, allowing water to pass rapidly through its wood cells. This characteristic helps prevent the formation of damaging moisture gradients during the drying process, which is a common concern in other wood species (Taylor & Mitchell 2007). Experience shows that southern pine wood can be dried rapidly and successfully at relatively high temperatures (Koch 1985). As temperature increases, the mass of water vapor, as indicated by saturated vapor pressure that air can hold, increases dramatically. For this reason, if lumber can be dried at increasingly high temperatures, less total air volume is required to remove the water. Moreover, the moisture content of freshly cut lumber can range from over 200% in the sapwood to as low as 30-35% in the heartwood, posing a challenge for the ensuing wood drying process. In pine species, sapwood has a moisture content between 128% and 160%, whereas hardwood has a moisture content ranging from 30% to 50% (Niemz et al. 2023).

Currently, no data is available for pilot-scale heated tube drying of southern yellow pine. Initial experiments suggest that heated tubes can effectively dry southern pine poles, lumber, and veneer. Moreover, smaller pieces of southern pine and possibly other wood species can likely be dried using this method. Demonstrating the advantages of employing heated tubes for wood product drying on a pilot scale can

which is shown in Tab. 1 was possible for the individual boards in each zone of the dryer. Temperature and residence time were variables of interest.

To charge each tube, four pieces of green specimens were aligned edge to edge, effectively making a 2 × 24 inches slab (about 5 × 61 cm). The four specimens were then inserted simultaneously into the dryer tube. Because the green specimens fit tightly into the tubes considerable ram force was required. To expedite dryer charging, a forklift was used to provide the necessary ram force. The process was repeated for the remaining tubes until all four tubes contained specimens. At that point, the 36 ft (≈ 11 m) long dryer contained specimens, each 12 ft (≈ 4 m) long. These specimens were in “zone 1” of the dryer. After a target amount of residence time, another set consisting of 16 pieces of 2 × 6 inches (≈ 5 × 15 cm) specimens were inserted into the four dryer tubes. The total duration (h) is calculated by summing the residence time in zones 1, 2, and 3 (Tab. 1). This additional set of specimens pushed the first specimens that were already in the dryer into “zone 2”. The process was repeated until the dryer was full. At full capacity, the dryer contained 48 pieces of lumber, equivalent to 48 ft³ (≈ 1.4 m³). Eventually all the pieces passed through all three zones of the dryer.

Data was collected on each individual board that was processed through the dryer. In the log breakdown process at the sawmill, the moisture in the wood is transferred to the sawn lumber, establishing the initial moisture content for the subsequent wood drying process. The initial weight of each green specimen was determined using a weighing scale. The final weight of the specimen was promptly quantified upon their exit from the heated tube dryer. Final MC of dried specimen was calculated using a moisture meter. The initial moisture content (MC_i, %) of the lumber was calculated based on the following equation (eqn 1):

$$MC_i = \frac{w_i}{w_{od}} \quad (1)$$

where w_i is the initial weight (lb) and w_{od} is the over dry weight (lb). Delta Moisture Content (ΔMC %) was calculated as follows (eqn. 2):

$$\Delta MC = MC_i - MC_f \quad (2)$$

where MC_i and MC_f are the initial and the final moisture content (%), respectively. Weight-loss rate (WLRs, lb/h) was calculated as (eqn. 3):

$$WLRs = \frac{W_i - W_f}{h} \quad (3)$$

where W_i and W_f are the initial and the final weight (lb), respectively, and h is the duration (in hours).

Aside from moisture content, lumber quality was not noted. Thus, warp as

crook, bow, or twist along with checking and other potential drying defects, were not tabulated. Once the rough lumber was dried it was returned to the cooperating sawmill for their subsequent further processing.

Statistical analysis

The experimental data underwent statistical analysis, utilizing an analysis of variance (ANOVA) along with Fischer’s F-Test, and Spearman Rank Order Correlations, employing STATISTICA™ version 14 software (StatSoft Inc., Tulsa, OK, USA).

Results and discussion

The results of the effects of average temperature (°F) and total duration (h) of drying time on ΔMC (%) and WLRs (lb/h) are shown in Tab. 2. It is evident from the P-values that the monitored factors, average temperature (°F) and total duration (h),

have a significant effect on the characteristics, ΔMC (%) and WLRs (lb/h).

Fig. 2 displays the ΔMC (%) of pine specimens dried with varying temperature zones over a period of times in the HTD. Notably, the highest ΔMC (78%) is observed in the temperature zones at 425-425-400 °F (≈ 218-218-204 °C) over a residence time of 6 h and 15 min. In contrast, at 400-400-350 °F (≈ 204-204-177 °C), ΔMC (%) is significantly lower, at 50%, at a residence time of 6 h and 30 min. Higher ΔMC (%) levels indicate greater amounts of moisture evaporated during HTD, while lower levels demonstrate less moisture evaporation. This result is interesting and suggests that the varying temperature at 425-400-400°F (≈ 218-204-204 °C) is the optimal choice for at 6 hours and 15 minutes residence time.

Another finding from the Fig. 2 is that 83% of all grouped samples (10 from all 12 groups) have a ΔMC ranging from 64% to

77.9%, while the remaining grouped samples (17%) have ΔMC values between 50% and 57% (based on the significant different in Tab. 3). The target was to achieve that 90% of all samples would be at or below

15%; 66% of the total samples are at or below 15%, while the remaining 33% are above 15%. All the pieces are dried together in a typical lumber dry kiln and in a shared commu-

nity atmosphere. There, temperature, humidity and airflow are regulated. As such the wetter pieces tend to dry more and the dryer pieces tend to dry less as they attempt to equilibrate with the atmosphere.

In the tube dryer, there was little atmospheric mixing adjacent to any specimen. Each tube contained a maximum of twelve isolated pieces. In each tube there was no direct control of humidity or air circulation. Additionally, initial lumber thickness, surface roughness, and shrinkage characteristics (which impact wood-to-platen contact) were considered sources of variation in the tube drying process.

The results of WLRs of pine specimens dried at varying temperature zones in HTD is demonstrated in Fig. 3. The highest weight loss-rate (WLRs = 4.5 lb/h, \approx 2 kg/h), was observed at varying temperature zones of 375-375-375 °F (\approx 191-191-191 °C), based on Tab. 4. at this zone, the Δ MC was 64.6% over a duration of 5:10 hours (Fig. 2). The higher WLRs are considered the best option for HTD.

The degrees of dependence between monitored factors (average temperature and total hours), and the analyzed characteristics (Δ MC and weight loss-rates) is shown in Tab. 5. The negative moderate degree of dependence was observed between WLRs and total duration. However, there was a weak degree of dependency between monitored factors and analyzed characteristics. This might relate to the lack of homogenous environment surrounding each specimen in the tube dryer. In many softwood mills, after cutting, some lumber goes straight to the kiln for drying. In other cases, the lumber is first left to air dry on the yard before going to the kiln. This creates different initial moisture levels when the kiln drying process begins.

Conclusion

The efficiency of a tube dryer on a pilot scale for southern yellow pine lumber was investigated. Over half of the total specimens were dried at or below a moisture content (MC) of 15%. Optimization of HTD's parameters, including drying temperatures and total duration, was achieved based on calculated characteristics Δ MC (%) and WLRs (lb/h). A low correlation was observed between the average temperature and Δ MC (%). Therefore, to be commercially effective, tube-dried lumber would likely have to be moisture sorted and a portion of it redried similar to the process flow of structural veneer drying, to achieve the desired moisture uniformity. Incorporating moisture sorting and redrying can improve lumber uniformity and benefit industries needing consistent quality. Future research should explore the effects of drying temperatures and duration on moisture content and investigate how integrating these processes can enhance the commercial viability of tube-dried lumber. Additionally, examining different wood species and conditions could expand the application of tube-type dryers.
